## ABSTRACT

We present wide-area radio continuum 5.5 and 8.8 GHz (5.5 and 3.4 cm) Australia Telescope Compact Array observations of the complex and rich massive star-forming region G305. The aim of this study is to perform an un-targeted survey of the region in search of the compact radio emission associated with ultracompact (UC) H II regions. Observations presented here encompass the entire complex and have a maximum resolution of  $\sim 1.5 \times 1.4$  arcsec and sensitivity of  $\sim 0.07$  mJy beam<sup>-1</sup>. By applying a data reduction method that emphasizes small-scale structure, we are able to detect 71 compact radio sources distributed throughout the observed field. To explore the nature of these compact radio sources we compare to mid-infrared data and in this way identify 56 background sources, eight stellar radio sources, a single bright-rimmed cloud and six candidate UC H II regions. The physical properties of these candidate UC H II regions are determined and reveal that five candidates have peak properties consistent with known UC H II regions with source radii ranging from 0.04 to 0.1 pc, emission measures from  $2.56$  to  $10.3 \times 10^{-6}$  pc cm<sup>-6</sup> and electron densities of  $0.34$ – $1.03 \times 10^4$  cm<sup>-3</sup>. We comment on these sites of recent massive star formation within G305 and by comparing to other star formation tracers (masers, NH<sub>3</sub> and young stellar objects) build a picture of the star formation history of the region. Using these results we estimate a lower limit to the star formation rate for the region of  $\sim 0.003$  M<sub>⊙</sub> yr<sup>-1</sup>.

**Key words:** stars: formation – ISM: clouds – H II regions – radio continuum: galaxies – radio continuum: ISM.

## 1 INTRODUCTION

The G305 star-forming complex is one of the most luminous H II regions in the Galaxy, comprising of a number of bright radio sources, with an integrated flux indicative of >30 deeply embedded O7 V stars (Clark & Porter 2004). The complex is located at  $l = 305^\circ 4$ ,  $b = 0^\circ 1$  and a heliocentric distance of  $3.8 \pm 0.6$  kpc placing it within the Scutum Crux arm of the Milky Way. Star formation appears to commenced with the formation of the two clusters Danks 1 and 2 approximately 3–6 Myr ago (Davies et al. 2012), and at the centre of the complex, the radiation and stellar winds from massive stars within these clusters appear to have excavated a cavity in the surrounding molecular material. Star formation is ongoing around

the periphery of this cavity with numerous H II regions, infrared hotspots, masers and dense molecular structure (Clark & Porter 2004; Hindson et al. 2010).

G305 contains several distinct sites and epochs of star formation in close proximity, which allows the investigation of massive star formation, evolution and the impact on the surrounding environment such as triggering (Elmegreen & Lada 1977; Habing & Israel 1979; Elmegreen 2002). The morphology of the region and position of star formation indicators suggest that interaction between the evolved massive stars, ongoing star formation and molecular material is taking place. Coupled with this, its relatively close distance makes G305 an excellent laboratory in which to carry out a multi-wavelength study of massive star formation. Our ultimate aim is to characterize the star formation history of the region and to evaluate the impact of the central cluster and massive stars on the current and future star formation.

\*E-mail: l.hindson@herts.ac.uk

A key observable feature in the evolution of a massive star is the radio emission associated with an H II region. These regions of ionized hydrogen form as the young massive star(s), still embedded in the natal molecular cloud, begins to ionize the surroundings via high-energy ultraviolet (UV) photons. As the H II region evolves and expands, it goes through the following observed evolutionary stages: hyper-compact, ultracompact, compact, classical and diffuse (Churchwell 2002). However, details of the evolutionary sequence and impact on the local environment are still poorly understood.

The ultracompact (UC) evolutionary phase of an H II region is defined as a small diameter ( $<0.1$  pc), high electron density ( $>10^4$  cm $^{-3}$ ) and high emission measure (EM;  $>10^7$  pc cm $^{-6}$ ) region of the ionized gas that surrounds the youngest and most massive O and B stars (Wood & Churchwell 1989a,b; hereafter WC89A and B). With an estimated lifetime of  $<10^5$  years (Comeron & Torra 1996; Davies et al. 2011), UCH II regions provide a direct tracer of one of the earliest stages of massive star formation.

Previous radio observations of G305 have either covered small areas at high resolution (e.g. around the methanol masers of Walsh et al. 1998) or were of low angular resolution and sensitivity (Goss & Shaver 1970; Caswell & Haynes 1987). Here we report on high resolution and sensitive observations of the 5.5- and 8.8-GHz radio continuum emission across the G305 complex. We aim to detect and estimate properties of a complete and unbiased sample of UCH II regions within the complex. We compare these observations to the clusters Danks 1 and 2, star formation tracers such as masers, young stellar objects (YSOs) and the dense molecular environment (Hindson et al. 2010, hereafter Paper I) to improve our understanding of the star formation mechanism(s) and history of the region.

This is the third in a series of papers aimed at studying massive star formation associated with this region. In two previous publications we have presented observations of the dense molecular material traced by NH $_3$  emission and star formation traced by H $_2$ O maser emission (Paper I) and high-resolution near-infrared observations of the evolved massive stars associated with the central clusters Danks 1 and 2 (Davies et al. 2012, hereafter Paper II).

In Section 2 we present details of the observations and data reduction process; in Section 3 we present our method for determining the nature of the detected radio emission through comparison with mid-infrared data. In Section 4 we derive physical properties of the candidate UCH II regions to determine if they are characteristic of UCH II regions. Section 5 presents our discussion of massive star formation within G305 and comparison with other star formation tracers and the dense molecular environment and in Section 6 we present a summary.

## 2 OBSERVATIONS AND DATA REDUCTION PROCEDURES

### 2.1 Observations

Observations of the radio continuum towards G305 were made using the Australia Telescope Compact Array (ATCA), which is located at the Paul Wild Observatory, Narrabri, New South Wales, Australia.<sup>1</sup> The ATCA consists of  $6 \times 22$  m antennas, five of which lie on a 3-km east–west (EW) railway track with the sixth antenna located 3 km further west. The array also has a 214-m north spur which

**Table 1.** Observational parameters for ATCA radio observations. Bracketed baseline ranges for the hybrid arrays represent the sixth antenna.

Array configuration	Date (dd/mm/yy)	Synthesized beam (arcsec)	Baseline range (m)
750B	26/02/10	$9.3 \times 10.5$	168–4500
1.5A	28/07/09	$4.8 \times 5.4$	153–4469
H75	10/07/09	$87.0 \times 87.0$	31–82(4408)
6A	06/06/09	$1.5 \times 1.4$	628–5939
H214	23/05/09	$33.6 \times 33.6$	92–247(4500)
H168	10/05/09	$40.8 \times 40.8$	61–192(4469)

allows for compact hybrid array configurations. The antennas can be positioned in several configurations with maximum and minimum baselines of 6 km and 30 m, respectively. We made use of six array configurations the EW 6A, 1.5A and 750B long baseline arrays and the H214, H168 and H75 hybrid arrays. The dates of observations and synthesized beams of each array can be found in Table 1.

The observations were made simultaneously at two intermediate frequency (IF) bands centred at 5.5 and 8.8 GHz and utilized the wide-band continuum mode of the new Compact Array Broadband Backend (CABB; Wilson et al. 2011). This resulted in a bandwidth of 2 GHz with  $2048 \times 1$  MHz channels in each IF. At the longest baseline of 6 km, we obtain a maximum resolution of  $1.5 \times 1.4$  arcsec and at the shortest baseline of 30 m, we are sensitive to emission on a scale of  $\sim 5$  and  $\sim 3$  arcmin at 5.5 and 8.8 GHz, respectively.

EW array observations were made over a 12-h period and hybrid array configurations over a 6-h period, providing good hour angle coverage. To correct for fluctuations in the phase and amplitude, caused by atmospheric and instrumental effects, the total scan time is split into blocks of 15 min of on-source integration sandwiched between 2-min observations of the phase calibrator 1352–63. For absolute calibration of the flux density the standard flux calibrator 1934–638 was observed once during the observation for approximately 10 min. To calibrate the bandpass the bright point source 1253–055 was also observed during the observations. In order to map the entire G305 region, at Nyquist sampling, the 8.8-GHz band required a mosaic of 357 individual points in a hexagonal pattern; this resulted in oversampling at 5.5 GHz. With a scan rate of 2 s point $^{-1}$  (spaced over a range of hour angles in order to improve  $uv$  coverage) we could thus complete a map in approximately 1 h and observe each pointing centre  $\sim 7$ –11 times for each hybrid and EW configurations, respectively, giving a total on-source integration time on each field of  $\sim 1$  min.

### 2.2 Data reduction

The calibration and reduction of the data were performed using the MIRIAD reduction package following standard ATCA continuum procedures. The reduction strategy described below is designed to emphasize the faint and compact radio emission ( $<3$  arcsec) associated with UCH II regions. We defer the analysis and discussion of the large-scale radio continuum structure of G305 to a following publication.

Our reduction strategy is as follows. Single fields were first Fourier transformed using multi-frequency synthesis mode to improve  $uv$  coverage and image fidelity. These individual dirty images were then imaged out to three times the primary beam ( $\sim 5$  arcmin at 8.8 GHz and  $\sim 8$  arcmin at 5.5 GHz) to account for emission from

<sup>1</sup> The Australia Telescope Compact Array is part of the Australia Telescope National Facility, which is funded by the Commonwealth of Australia for operation as a National Facility managed by CSIRO.

bright sources outside of the primary beam main lobe. These maps were produced with a pixel size that samples the synthesized beam by three pixels and a robust weighting of 0.5, as opposed to natural or uniform, in order to reduce side lobe levels and produce a uniform synthesized beam shape at the sacrifice of some sensitivity.

An unfortunate consequence of mapping such a large area is the snapshot nature and consequent sparse  $uv$  sampling of individual fields. This introduces significant artefacts, such as rippling, side lobes and dark bowls in fields coincident with complex and bright large-scale emission (Taylor, Carilli & Perley 1999). These artefacts can easily be confused with real compact emission and results in the localized noise being up to three times higher towards bright large-scale emission. We are interested in detecting the compact radio emission associated with UCH II regions and these artefacts as well as the bright extended emission hamper this goal. Therefore, to emphasize small-scale structure and remove artefacts, all baselines  $< 15$  k $\lambda$  were cut (cf. Kurtz, Churchwell & Wood 1994; Mücke et al. 2002) from the  $uv$  data set, which results in the removal of all flux associated with the large-scale emission  $\gtrsim 0.2$  arcmin. As a result, the integrated flux of resolved sources may be underestimated by as much as 50 per cent and should be considered as a lower limit. This removal of the extended flux does not significantly affect the main goal of this study and is deemed an acceptable consequence of the improved data reduction and compact source detection.

With the large-scale emission removed, the compact emission dirty maps could be more easily cleaned. A cut-off level of  $3 \times \sigma$ , where  $\sigma$  is the standard deviation of the noise in each image, was selected, resulting in a few hundred to few thousand clean components depending on the emission in the image. Finally, the 357 individual restored fields were stitched together using the linear mosaic task `LINMOS`. In this mosaic we obtain a sensitivity of 0.07 and 0.15 mJy beam $^{-1}$  for the 5.5- and 8.8-GHz maps, respectively, and a dynamic range of  $\sim 1000$ .

The final compact radio mosaic was analysed in the following way. The peak flux densities and coordinates were determined using the task `MAXFIT` in `MIRIAD`. For unresolved and spherical sources, the integrated flux density and size were determined by fitting a Gaussian using the task `IMFIT`. In the case of sources that are resolved and not well fitted by a Gaussian, we determine the integrated flux densities and sizes by carefully fitting irregular-shaped apertures around the sources and extracting the flux.

### 3 SOURCE CLASSIFICATION

The radio emission detected at 5.5 and 8.8 GHz is not only generated by the thermal free-free emission associated with H II regions but may also originate from a number of astronomical sources; for instance, thermal emission from stellar winds (Kenny & Taylor 2007), bright-rimmed clouds (BRCs; Thompson, Urquhart & White 2004) and non-thermal emission from colliding wind binaries (Dougherty et al. 2003), pulsars (Lazaridis et al. 2008), supernova remnants (Gaensler et al. 1997) and active galactic nuclei (Soria et al. 2010). In the following section, we describe how we separate candidate UCH II regions from these contaminating sources by using ancillary mid-infrared data.

In Fig. 1 we present a mid-infrared image of the G305 region that shows the distribution of the detected compact radio sources. These are randomly distributed across the field, which would suggest that many are background sources, rather than being associated with G305. In Table 2 we present the positions and derived properties of the 71 compact radio sources identified from our radio data. Several sources are not detected in the lower sensitivity 8.8-GHz maps and

for these sources we present the upper limit  $3\sigma$  flux level. We find that the majority of radio sources detected are unresolved (59) and given that the majority of UCH II regions presented in the literature are resolved at similar resolutions (e.g. Wood & Churchwell 1989b; Kurtz et al. 1999; Urquhart et al. 2007, 2009), it is likely that most of these unresolved sources are extragalactic in origin.

To explore the nature of the detected radio emission we extract images from the *Spitzer* telescope Galactic Legacy Infrared Mid-Plane Survey Extraordinaire (GLIMPSE; Benjamin et al. 2003; Churchwell et al. 2009). The GLIMPSE survey utilizes the InfraRed Array Camera (IRAC; Fazio & Hora 2004) on *Spitzer* to map emission at 3.6, 4.5, 5.8 and 8.0  $\mu$ m with a spatial resolution of  $\sim 2$ -arcsec full width at half-maximum (FWHM) well matched to the observations presented here. The four IRAC bands trace different physical properties and so an analysis of these provides a means to infer the origin of the radio emission. The 3.6- $\mu$ m band is dominated by field stars, while an excess in the 4.5- $\mu$ m band is thought to arise from shocked molecular hydrogen and CO bandheads, possibly indicating the presence of an outflow. The 5.8- and 8.0- $\mu$ m IRAC bands are dominated by strong polycyclic aromatic hydrocarbon (PAH) features that are excited in the photodominated regions (PDRs) that lie in a thin shell of neutral gas located between an ionization front and cold molecular gas.

To take advantage of the sensitivity to different physical phenomenon we have created false three-colour images, centred on the 5.5-GHz peak, using the 4.5-, 5.8- and 8.0- $\mu$ m IRAC bands in blue, green and red, respectively (cf. Cohen et al. 2007; Urquhart et al. 2009). From a visual examination of these images, we find that the radio sources can be separated into four distinct categories. In Fig. 2 we present an example of each of these and describe the main features of each category below.

(i) Radio emission is coincident with strong compact mid-infrared emission, which is itself associated with extended PAH emission and/or extinction, which are commonly associated with star formation regions. These are considered UCH II candidates (Fig. 2, top-left).

(ii) Radio and mid-infrared emissions are both unresolved and correlated, and the mid-infrared emission is dominated by the shorter (blue) wavelengths. We consider that the radio emission seen towards these sources arises from a stellar source. Additionally, these radio and mid-infrared sources are often isolated, which suggests that they are not associated with star formation. (Fig. 2, top-right).

(iii) We classify a source as a BRC if the radio and mid-infrared emissions have a similar cometary morphology with no obvious core and the radio emission is offset from the mid-infrared emission (Fig. 2, bottom-left).

(iv) Radio sources that are devoid of any mid-infrared emission are assumed extragalactic radio sources. A large proportion of the unresolved radio sources fall into this category (Fig. 2, bottom-right).

We derive the spectral index ( $\alpha$ ) of sources by taking the logarithm and fitting a straight line to the relation  $S_{\text{int}} \propto \nu^\alpha$ , where  $S_{\text{int}}$  is the integrated flux and  $\nu$  is the frequency. To search for non-linear variation of flux with frequency we split the full 2-GHz bandwidth into 1-GHz wide bands centred at 5.0, 6.0, 8.3 and 9.3 GHz and generate images following the steps outlined in Section 2.2. Given the errors we find no convincing evidence of non-linear spectral energy distributions (SEDs). As mentioned in Section 2.2, the integrated flux for resolved sources is a lower limit and cannot be reliably estimated; in addition, the

**Figure 1.** The 71 compact 5.5-GHz radio sources are overlaid on to a 5.8- $\mu$ m GLIMPSE image. White diamonds indicate candidate UCH II regions, blue triangles show stellar sources, black crosses show background sources and a green star highlights the BRC.

$uv$  plane has been sampled differently at the two frequencies, as the ATCA is not a scaled array, and so the flux cannot be reliably compared. For these reasons the spectral index cannot be determined reliably for resolved sources and is presented for only the unresolved and isolated sources.

We will further consider the UCH II region candidates in the next section. For the remainder of this section we briefly discuss the other classes of objects discovered.

We find that eight of the 71 radio sources (Fig. 2) are associated with more evolved stars (isolated, unresolved and possessing blue colours). Approximately half of these stellar sources are found towards the centre of G305 and are associated with well-known evolved massive stars. Two sources, 2 and 59, are associated with the most massive members of Danks 1 (D1-1 and D1-2), whilst Source 3 is associated with the Wolf-Rayet star WR 48A and Source 56 with the massive star MDM3 (Paper II). An examination of the

spectral index reveals that the radio emission associated with six stellar sources is positive (2, 3, 56, 59, 63 67) and only two are negative (11, 60). Sources with a positive spectral index are most likely generating thermal emission associated with an ionized stellar wind, whilst negative spectral index sources are most likely generating non-thermal emission via wind shocks or colliding winds from binary stars (Dougherty et al. 2003). Further analysis of these sources is beyond the scope of this study.

BRCs are found on the edge of evolved H II regions where the ionizing radiation emitted from an OB star(s) ionizes the surface of a molecular cloud (Sugitani, Fukui & Ogura 1991; Thompson et al. 2004). This molecular material is often swept into a cometary morphology by the radiation pressure and results in a dense core at the head that shields the remaining cloud material, resulting in a finger or column. Comparison with mid-infrared data reveals Source 10 has this characteristic morphology and is found on the

**Table 2.** Identifiers and observed properties of the 71 detected compact radio sources. For sources that fall below the detection limit at 8.8 GHz we present the upper limit  $3\sigma$  value, where  $\sigma$  is the rms noise, indicated by  $\uparrow$ . A superscript above the source index indicates the nature of the source as derived in Section 3, ‘st’ corresponds to stellar, ‘uc’ corresponds to UC H II candidate and ‘brc’ refers to bright-rimmed cloud; sources with no superscript are background. The spectral index is derived from the 1-GHz split data set and presented for unresolved sources only.

**Figure 2.** Three colour 4.5-, 5.8- and 8.0- $\mu\text{m}$  composite GLIMPSE (blue, green and red, respectively) cut-out images centred on the peak 5.5-GHz radio emission with contours beginning and incrementing by  $3\sigma$ . An example of a UCH II region (top left), stellar (top right), BRC (bottom left) and background galaxy (bottom right) is shown. These are classified following the criteria outlined in Section 3. The beam is presented in the lower left corner of each image.

inner borders of a shell of diffuse 5.8- $\mu\text{m}$  emission that has been identified as an evolved H II region (Caswell & Haynes 1987; Clark & Porter 2004). The cometary morphology of the radio and mid-infrared emission points to an ionizing source to the east of the BRC towards the centre of the evolved H II region. Compelling candidates for the source of ionization are found within the H II region in the massive star L05-A2 (table 2 in Paper II) and a deeply embedded infrared excess cluster (Longmore et al. 2007).

As previously mentioned, we failed to associate the majority of radio sources with any mid-infrared emission and these are assumed extragalactic background sources. To test this assumption it

is useful to compare the number in this category with the estimated number of background radio sources ( $\langle N \rangle$ ) one would expect given the size of the observed region and the frequency at which the observations were performed. We can estimate this number empirically from extragalactic source counts using the following equation from Anglada et al. (1998):

$$\langle N \rangle \simeq \left( \frac{\theta_f}{\theta_A} \right) 1.1 S_0^{-0.75}, \quad (1)$$

where  $\theta_f$  is the diameter of the observed field,  $\theta_A$  is the FWHM of the primary beam in arcminutes and  $S_0$  is the sensitivity at 5.5 GHz.

**Figure 3.** Three colour 4.5-, 5.8- and 8.0- $\mu\text{m}$  composite GLIMPSE (blue, green and red, respectively) cut-out images centred on the peak 5.5-GHz radio emission of the six candidate UCH II regions. The first panel shows a wide field of view image with a cyan box centred on the peak of the radio emission. The second panel shows the outlined field of view with the cyan box. Black contours are of the 5.5-GHz radio emission with contours beginning and incrementing by  $3\sigma$ . Sources are coincident with mid-infrared emission indicative of an embedded stellar source (see criteria in Section 3). The beam is presented in the lower left corner of each image.

Using this equation we estimate that  $\sim 60 \pm 8$  background sources should be detected in the  $\sim 1.0^\circ \times 1.0^\circ$  field. From our comparison with the mid-infrared we find 56 compact radio sources that fit the criteria of extragalactic sources, which is in good agreement with the result obtained above from equation (1). These background sources are mainly unresolved point sources but there are a number of resolved sources that exhibit lobes of emission similar to the radio lobes seen in active radio galaxies (Fig. 2, bottom-right). We expect to find a negative or flat spectral index for background radio galaxies associated with non-thermal radiation and we find this is the case. Only nine of these background sources have  $\alpha > -0.1$ , consistent with optically thick thermal free-free emission, while 42 have  $\alpha < -0.1$ , indicating a non-thermal emission mechanism.

#### 4 PHYSICAL PARAMETERS OF UCH II REGIONS

In the previous section, we described how mid-infrared data were used to separate the compact radio sources into four distinct categories. We identified six sources that appear to be good candidates for classification as UCH II regions (see Fig. 3 for mid-infrared three-colour images of these). In this section, we will determine the physical properties of these candidate UCH II for comparison with bona fide UCH II regions reported in the literature.

In the following analysis, we assume that the origin of the radio emission is free-free (bremsstrahlung), optically thin and thermal arising in an ionized circumstellar environment. This assumption must be treated with caution as the opacity of a typical UCH II

**Table 3.** Derived source properties for candidate UCH II regions.

Source index	Source name	Radius (pc)	$T_b$ (K)	$\tau$ ( $10^{-3}$ )	$n_e$ ( $10^4 \text{ cm}^{-3}$ )	EM ( $10^6 \text{ pc cm}^{-6}$ )	$M_{\text{HII}}$ ( $10^{-3} M_\odot$ )	$\log N_{\text{Ly}}$ ( $\text{s}^{-1}$ )	$M_*$ ( $M_\odot$ )	Spectral type
8	G305.362+00.150	0.04	770.0	80.03	1.03	8.76	74.0	46.62	13.8	B0.5

26	G304.930+00.552	0.07	77.0	7.72	0.25	0.84	84.0	46.02	12.0	B1
37	G305.200+00.019	0.04	230.0	23.34	0.58	2.56	32.0	46.12	12.3	B1

region with  $\text{EM} > 10^7 \text{ pc cm}^{-6}$ , diameter of  $\sim 0.1 \text{ pc}$  and electron density  $> 10^4 \text{ cm}^{-3}$  is found to turn over from optically thin to optically thick below 5 GHz (Kurtz 2005). To test the validity of this assumption we derive the physical properties using both the 5.5- and 8.8-GHz data and find they agree to within a factor of 2, which would suggest that the assumption of optically thin emission at 5.5 GHz is valid. We therefore only report the properties derived from the higher signal-to-noise ratio 5.5-GHz data.

As mentioned in Section 2.2, the integrated flux of resolved compact radio sources is underestimated due to the removal of short baselines used to emphasize small-scale structure. The peak emission of sources is unaffected by the removal of short baselines and so we derive the peak ( $\text{mJy beam}^{-1}$ ) properties, averaged over the area of the synthesized beam, following the method of WC89A. The beam brightness temperature is estimated from:

$$T_b = \frac{S_\nu 10^{-29} c^2}{2\nu^2 k \Omega_b} \text{ (K)}, \quad (2)$$

where  $S_\nu$  is the peak flux density ( $\text{mJy beam}^{-1}$ ),  $\nu$  is the frequency (Hz),  $c$  is the speed of light ( $\text{m s}^{-1}$ ) and  $\Omega_b$  is the beam solid angle ( $3.36 \times 10^{-11} \text{ sr}$  at 5.5 GHz). The peak optical depth  $\tau$  is estimated using  $T_b = T_e(1 - e^{-\tau})$  assuming the beam is uniformly filled with ionized gas. The electron temperature of the ionized gas within H II regions has been shown to vary between 6800 and 13 000 K (Spitzer & Savedoff 1950; Caswell & Haynes 1987). The electron temperature towards regions in G305 is unknown and so we assume a value of  $T_e = 10^4 \text{ K}$  throughout the rest of this analysis. This assumption results in an uncertainty of  $\sim 20$  per cent in the derived optical depth and  $< 10$  per cent in the physical properties derived below. The optical depth  $\tau$  may be written as

$$\tau = -\ln \left( 1 - \frac{T_b}{10^4} \right). \quad (3)$$

We calculate the peak EM from the expression of the optical depth  $\tau$  for free-free radiation:

$$\text{EM} = \frac{\tau}{8.235 \times 10^{-2} T_e^{-1.35} \nu^{-2.1}} \text{ (pc cm}^{-6}\text{)}, \quad (4)$$

where the frequency is expressed in GHz. The electron density ( $n_e$ ) is given by

$$n_e = \sqrt{\frac{\text{EM}}{\Delta s}} \text{ (cm}^{-3}\text{)} \quad (5)$$

where  $\Delta s$  is the optical path length through the peak and is defined as the geometrical average of the two axes of the source after applying the correction of Panagia & Walmsley (1978). We estimate the peak ionized gas mass ( $M_{\text{HII}}$ ) by multiplying the peak electron density by the proton mass and volume of the emitting region assuming spherical morphology.

The remaining physical properties ( $N_{\text{Ly}}$ ,  $M_*$  and spectral type) have been derived using the integrated flux and it is important to

reiterate that since the integrated flux is underestimated these properties should be considered lower limits. The total ionizing photon flux of the Lyman continuum ( $N_{\text{Ly}}$ ) is independent of source geometry and is determined using the modified equation (7) presented in Carpenter, Snell & Schloerb (1990):

$$N_{\text{Ly}} = 7.7 \times 10^{43} S_{\text{int}} D^2 \nu^{0.1} \text{ (s}^{-1}\text{)}, \quad (6)$$

where  $N_{\text{Ly}}$  is the total number of Lyman photons emitted per second,  $S_{\text{int}}$  is the integrated radio flux ( $\text{mJy}$ ),  $D$  is the distance to the source ( $3.8 \pm 0.6 \text{ kpc}$ ) and  $\nu$  is the frequency of the observation (GHz). This value of the ionizing flux should be considered a lower limit due to dust absorption of the UV flux and the underestimated integrated flux.

We are able to estimate the mass of the ionizing source ( $M_*$ ) responsible for the observed Lyman flux by interpolating between the calculated values of mass and Lyman flux presented in table 1 of Davies et al. (2011). The values in this table were computed by combining the results from stellar atmosphere models by various authors, see Davies et al. (2011) for more details. The resultant masses are presented in column 10 of Table 3 and should be treated as a lower limit with errors of  $\sim 30$ – $50$  per cent caused by the calibration of Lyman flux to ionizing source mass (Davies et al. 2011).

We estimate the spectral type of the ionizing star by comparing the estimated Lyman continuum flux to the derived value of the total number of ionizing photons generated by massive stars tabulated by Panagia (1973). We assume the radio emission observed is caused by a single zero-age main-sequence (ZAMS) star, assuming no UV flux is absorbed by dust and that the H II region is ionization bounded. Whilst the most massive star will dominate the Lyman flux if there are multiple stars that make a significant contribution to the ionizing flux, the spectral type will be later than we have estimated. Conversely, if there is significant absorption by dust and/or the nebular is not ionization bounded, the spectral type may be earlier than our estimate.

The physical properties determined for all but one of the candidate UCH II regions in Table 3 are typical of UCH II regions described in the literature, e.g. small diameter ( $< 0.1 \text{ pc}$ ), high electron density ( $> 10^4 \text{ cm}^{-3}$ ) and high emission measure ( $> 10^7 \text{ pc cm}^{-6}$ ). We find that the derived physical properties for Source 26 are significantly lower than those for the other candidate UCH II regions. Moreover, a comparison with the  $\text{NH}_3$  emission maps (Paper I) reveals a lack of dense gas towards Source 26 that would indicate that the region is either a more evolved H II region having already dissipated its natal cloud or has another origin. Visual examination of the mid-infrared image of this source, presented in Fig. 3, reveals that the radio emission is actually offset from the bright mid-infrared source that dominates the image. It is possible that this radio emission is in fact another extragalactic background source and we have therefore removed Source 26 from the list of UCH II regions.

For the five remaining sources we find radii ranging from 0.04 to 0.11 pc, electron densities in the range of  $0.34\text{--}1.03 \times 10^4 \text{ cm}^{-3}$  and emission measures at  $2.56\text{--}10.3 \times 10^6 \text{ pc cm}^{-6}$ . These values correspond to UCH II regions in the classification scheme of Kurtz (2002) and WC89A and B. Based on the correlation with mid-infrared emission and derived physical properties, we classify the compact radio sources 8, 9, 17, 20 and 37 as UCH II regions.

## 5 DISCUSSION

In this section we will look at the distribution of UCH II regions found towards G305 with respect to the overall structure of the complex and the other star formation tracers that have been reported in the literature. To help facilitate the following discussion we present a GLIMPSE 5.8- $\mu\text{m}$  image of the G305 complex in Fig. 4. On this image we show the distribution of UCH II regions, dense gas as traced by the  $\text{NH}_3$  (1, 1) and (3, 3) inversion transition and water masers presented in Paper I, methanol masers identified by the Methanol Multibeam (MMB) survey (Green et al. 2009) and massive young stars identified by the Red *MSX* Source (RMS; Urquhart et al. 2008b) survey.

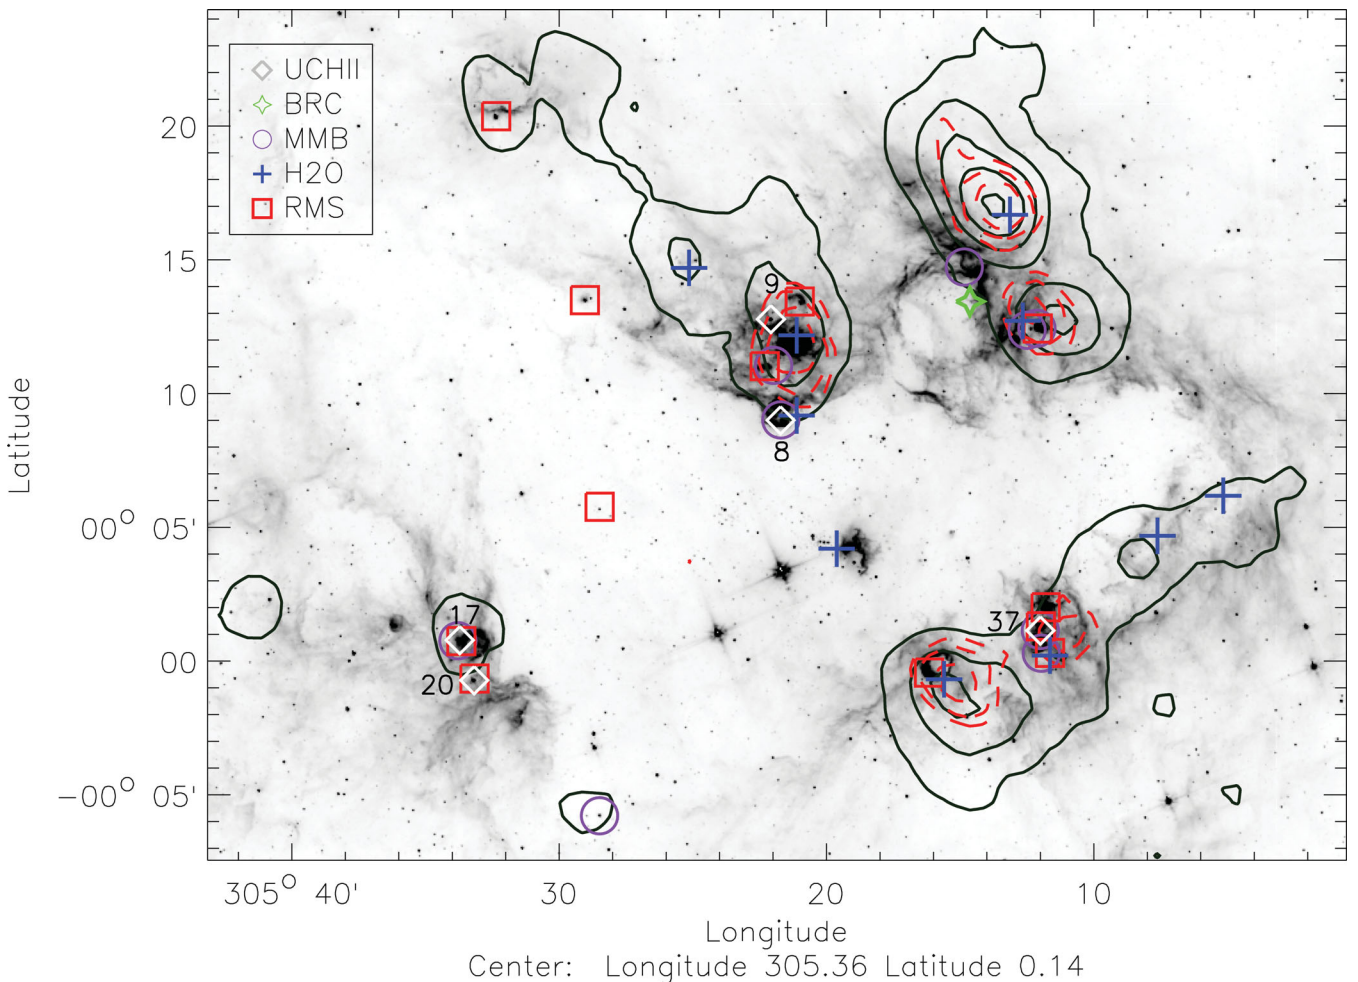

### 5.1 Distribution of UCH II regions

We find that all five UCH II regions are located around the inner rim of the central cavity, within the PDR, towards areas where the mid-infrared emission is bright and compact (Fig. 4). We find no evidence of UCH II regions within the central cavity, outside the bounds of the PDR or towards the G305.2+0.2 region. Although all five UCH II regions are resolved we find four possess very simple morphology, primarily consisting of a very compact core which is associated with some low-surface-brightness diffuse emission and one source with an irregular distribution. The lack of structure seen towards the majority of these radio sources may suggest that they are still at a very early stage of their evolution.

### 5.2 Comparison to $\text{NH}_3$ , masers and RMS data

To explore the environment and high-mass star formation within G305, we compare the UCH II regions detected in this study to the dense molecular environment and star formation tracers taken from the literature.

Comparing the positions of the UCH II regions with respect to the dense molecular clouds located on the periphery of G305 we find

**Figure 4.** GLIMPSE 5.8- $\mu\text{m}$  background with the locations of UCH II regions (white diamonds), RMS survey sources (red squares),  $\text{H}_2\text{O}$  masers (blue crosses), methanol masers (purple circles) shown. Dense gas is traced by  $\text{NH}_3$  (1, 1) and (2, 2) contours in black and red, respectively, starting at  $3\sigma$  and  $9\sigma$  and incrementing by  $3\sigma$  and  $2\sigma$ , respectively, where  $\sigma$  is the rms noise in the velocity-integrated  $\text{NH}_3$  maps ( $\sim 0.01 \text{ K}$ ).

four are located within the borders of the  $\text{NH}_3$  (1, 1) emission offset from the peak within the lower density region facing the central cavity. Source 9 is an exception as it appears to be embedded within a dense  $\text{NH}_3$  clump; however, as mentioned in Paper I, this could be a projection effect and we may be viewing the cloud face on. We find that three sources (8, 9 and 37) are also on the borders of the higher excitation  $\text{NH}_3$  (3, 3) transition. Furthermore, we find that the  $\text{NH}_3$  clouds associated with UCH II regions have higher kinetic temperatures and line widths than clouds with no detectable UCH II region. This result is in agreement with studies such as Urquhart et al. (2011b), where 80 per cent of massive star formation sites are associated with  $\text{NH}_3$  emission.

Water and methanol masers are both well correlated with star formation (Urquhart et al. 2011b; Menten 1991) and are thought to be associated with the very earliest stages (i.e. prior to the formation of an H II region). We make use of the  $\text{H}_2\text{O}$  masers detected in Paper I which have a positional accuracy of  $<20$  arcsec (Walsh et al. 2011) and methanol masers from the MMB survey (Caswell 2009; Green et al. 2009, 2012) which have a positional accuracy of 0.1 arcsec.

We find nine 6.67-GHz methanol masers within the field of view of G305 presented in Fig. 4. Three of these methanol masers are associated with UCH II regions (8, 17 and 37) and are offset from the peak of the radio emission by  $\lesssim 0.1$  pc. This suggests that they are associated with a nearby young stellar source rather than the UCH II region itself. It is unclear why two UCH II regions (9 and 20) have no methanol maser emission but it could indicate that they are older (Ellingsen et al. 2007) and methanol masers have switched off. UCH II regions with no methanol maser emission are found to have sizes approximately twice that of those with methanol maser emission, although caution should be taken as the diffuse emission has been removed in the data reduction. This also assumes that Source 17 comprises more than one UCH II region, as suggested by the morphology, and indicates that the UCH II regions associated with methanol masers are younger than those that are not. Looking at the mid-infrared (Fig. 3) it can be seen that the UCH II regions with methanol masers are associated with bright extended mid-infrared emission compared to UCH II regions without, which are found to be associated with isolated mid-infrared emission. There are six methanol masers that have no associated compact radio emission, which indicates that there is ongoing massive star formation in the region, embedded within the dense molecular gas, that have yet to create an observable UCH II region.

In Paper I, we present 16 22-GHz  $\text{H}_2\text{O}$  (6–5) masers (table 5 in Paper I) towards G305. We find that these  $\text{H}_2\text{O}$  masers are anti-correlated with the position of UCH II regions. Comparison with the  $\text{NH}_3$  data reveals that the  $\text{H}_2\text{O}$  masers are found predominantly embedded within the dense molecular clouds. This is consistent with the view that  $\text{H}_2\text{O}$  masers are tracing a younger evolutionary state than methanol masers and UCH II regions before the formation of a detectable H II region when the source is still deeply embedded as suggested by Garay & Lizano (1999).

Searching the RMS data base (Urquhart et al. 2008b)<sup>2</sup> we find 14 young massive stars (i.e. H II regions or YSOs) that are positionally and kinematically associated with the G305 complex.<sup>3</sup> The RMS survey is limited by the resolution and sensitivity of the MSX satellite, which results in a detection limit of YSOs with a luminos-

ity of  $>10^3 L_\odot$  and mass of  $>7 M_\odot$  (see fig. 5 of Urquhart et al. 2011a). This sample of RMS sources highlights regions of recent massive star formation and these can be clearly seen to be associated with the PDR and the dense molecular gas in Fig. 4. We find that RMS survey H II regions match the following UCH II sources detected here: 8, 17, 20 and 37; this further confirms their status as UCH II regions. Source 9 has no RMS detection, which is likely due to its close proximity to a very bright evolved H II region and the limited resolution of MSX. We find that all but one of the RMS survey sources are found around the rim of G305 some distance from the central clusters Danks 1 and 2. We are currently investigating the low-mass YSO component of G305 using *Herschel* infrared Galactic Plane Survey (Hi-GAL) (Faimali et al., in preparation) data and a YSO counting approach similar to the Povich et al. (2011) study of Carina.

In a study carried out by Walsh et al. (1997, 1998), the detection of five UCH II regions is reported towards G305; we find that only one of these matches those detected here (Source 17). This contradiction most likely arises because of a combination of the *IRAS* selection criteria used by Walsh et al. and the relatively short snapshot nature of their interferometry follow-up observations. With its limited resolution ( $\sim 2$  arcmin), the *IRAS* selection has most likely mistaken more evolved compact H II regions, which appear unresolved, for UCH II regions. The snapshot nature of the follow-up radio observations (Walsh et al. 1998) has then appeared to result in the peaks of evolved H II regions being mistakenly identified as UCH II regions. Work carried out by Longmore et al. (2007) found embedded infrared excess sources towards the G305.2+0.2 region. We find no compact radio emission associated with these young stellar sources or the G305.2+0.2 region. However, we do find evidence of interaction between the massive stars and molecular material in the region, as predicted by Longmore et al. (2007), in the BRC (Source 10) and also the enhancement of star formation indicators found along the boundary between ionized and neutral material of G305.2+0.2 (Fig. 4).

### 5.3 Star formation within G305

It is clear that massive star formation is ongoing within G305 with the UCH II regions that we have identified providing evidence of at least five massive stars forming in the last few  $10^5$  years. In addition, RMS sources methanol and  $\text{H}_2\text{O}$  masers indicate many additional sites of massive star formation. These massive star formation tracers are primarily restricted to the periphery of the central cavity within the boundary of the dense molecular gas and PDR towards regions where the mid-infrared emission is bright and compact.

Considering the distribution of stars and star formation across the G305 region, we can draw a broad-brush picture of the star formation history of G305. In the initial stages the central parts of the natal Giant Molecular Cloud (GMC) collapsed to first form Danks 2 ( $\sim 3$  Myr ago) and then Danks 1 ( $\sim 1.5$  Myr ago; Paper II). For the last  $\sim 3$ –6 Myr, the powerful UV radiation and winds from their population of massive stars have swept up the surrounding molecular material into the morphology we see in Fig. 4. During this time, a second generation of massive stars has formed, apparent by the presence of more evolved H II regions (Clark & Porter 2004), around the cavity. Whether the massive stars responsible for these H II region were spontaneous or induced to form is uncertain.

It is around these H II regions that we find evidence of the most recent episodes of massive star formation traced by UCH II regions and methanol masers.  $\text{H}_2\text{O}$  maser emission towards the cores of  $\text{NH}_3$  emission indicates that younger epochs of high- and/or

<sup>2</sup> <http://www.ast.leeds.ac.uk/RMS/>

<sup>3</sup> <sup>13</sup>CO observations taken by the RMS survey team towards these sources show their velocities are well matched to the global velocity of G305 (Urquhart et al. 2008a).

low-mass star formation are taking place deeply embedded within the dense molecular material further still from the central cavity. Thus, it appears that the star formation in G305 is multi-generational and has at least partly occurred in spatially and temporally isolated bursts.

The morphology of the mid-infrared emission, dense molecular gas and the location of star formation tracers are suggestive of triggered star formation as proposed by Elmegreen & Lada (1977). Recent and ongoing star formation is enhanced and concentrated around the borders of four evolved H II regions (Clark & Porter 2004; 305.551–0.005, 305.363+0.179, 305.254+0.204 and 305.202+0.002) between ionized and molecular gas. However, the morphology of a star-forming region is not considered sufficient evidence for triggered star formation since it may be that the radio- or wind-blown bubble is simply uncovering already existing star formation. In this regard, our unbiased multi-wavelength data sets, encompassing the whole G305 complex, are particularly valuable in distinguishing between these possibilities via the identification of high- and low-mass YSOs.

If star formation were sequential, one would expect to find YSOs interior to the cavity but none outside, whereas they should be distributed throughout the GMC if this was not the case (cf. Smith et al. 2010). The star formation, including YSOs ( $>7 M_{\odot}$ ), identified by the RMS survey is found outside of the central cavity with exception to one source that is found at a projected distance of  $>10$  pc from the centre of the complex. This phenomenon is also observed in Carina, where the YSOs are found to be concentrated towards the edges of bright rims (Preibisch et al. 2011).

We should note that there is one site of star formation observed towards the cavity centre, a H<sub>2</sub>O maser that is associated with diffuse mid-infrared emission. However, this object is likely located on the far or near side of the cavity, rather than within the central cavity itself, as there is no evidence in the mid-infrared morphology of any interaction with the winds from WR 48A, Danks 1 or Danks 2.

Further evidence of triggering is suggested by the interaction between the ionized and molecular material particularly in the G305.2+0.2 region where the BRC Source 10 can be found. Whilst these observations are suggestive of triggering further study of the low-mass YSO component, as mentioned in Section 5.2, and the interaction between the large-scale radio emission associated with evolved H II regions and molecular material of G305 is essential for any determination of the global properties and to further explore the effect of massive star feedback in the region.

#### 5.4 The current star formation rate in G305

In Paper II we determined the mass and age of the two central stellar clusters Danks 1 and 2, which are  $8000 \pm 1500$ ,  $3000 \pm 800 M_{\odot}$  and  $1.5^{+1.5}_{-0.5}$ ,  $3^{+3}_{-1}$  Myr, respectively. If we make the assumption that the star formation within these clusters has proceeded constantly over their lifetimes, then these masses and ages imply star formation rates of  $\sim 10^{-3}$ – $10^{-2} M_{\odot} \text{ yr}^{-1}$ , i.e. at a similar rate as to the Carina complex (Povich et al. 2011). In this section, we use our UC H II region detections to estimate the current star formation rate in G305 so that we may compare the current star formation rate to that of Danks 1 and 2.

Before doing so we will briefly dwell upon the caveats involved in this calculation. First, the stars powering the UC H II regions are by definition massive and thus we are forced to extrapolate the number of lower mass stars by integrating over the initial mass function (IMF). Secondly, the time-scale for this star formation is not well known and will vary across the IMF from high mass to

low mass. Low-mass stars take  $\sim 0.5$  Myr to reach the pre-main-sequence (PMS) phase (i.e. the stage at which most of their stellar mass is assembled; Evans et al. 2009; McKee & Offner 2010; Offner & McKee 2011), whereas the higher mass stars that are the source of the ionizing photons powering the UC H II regions reach the main sequence while still accreting. Both of these errors likely dominate over the error in determining the radio luminosity of the UC H II regions due to the uncertain distance of G305 ( $3.8 \pm 0.6$  kpc; Paper II).

However, obtaining even an order of magnitude estimate for the current star formation rate is instructive to compare with that determined for Danks 1 and 2. Large differences in the star formation rate may indicate that the influence of Danks 1 and 2 is either enhancing or suppressing star formation in the surrounding cloud. Our estimated star formation rate can also be compared with other star-forming complexes, such as Carina, to place G305 in context with the rest of the Milky Way.

To derive the current star formation rate over the past 0.5 Myr we assume that for each of our five UC H II regions, the most massive star present (shown in Table 4) produces the majority of the ionizing photon flux and is accompanied by a cluster of lower mass stars or YSOs. We then determine the total mass of stars and YSOs that may be present by extrapolating over a Salpeter IMF (Salpeter 1955) fixed to the mass of the most massive star in each UC H II region. We assume an upper and lower mass limit of 50 and  $0.1 M_{\odot}$  (Robitaille & Whitney 2010).

This extrapolation yields a total number of  $\sim 1 \times 10^3$  stars or YSOs, which corresponds to a total stellar mass of  $1.5 \times 10^3 M_{\odot}$ . This is of the same order of magnitude as the mass in each of the Danks clusters and similar to the number of YSOs detected in a recent study of the Carina complex (Preibisch et al. 2011). As a consistency check, we compared the number of the massive YSOs (i.e.  $L > 10^3 L_{\odot}$ ) predicted by our IMF to the number of massive YSOs observed in the complex by the RMS and MMB surveys and found an agreement to within a factor of 2.

Assuming that the stars or YSOs have formed constantly over the last 0.5 Myr, this implies an average star formation rate of  $\sim 0.003 M_{\odot} \text{ yr}^{-1}$ . We consider this rate to be a lower limit due to the likely incompleteness of our survey for UC H II regions located near to the bright and extended classical H II regions within G305, and also the fact that the  $uv$  cut described in Section 2.2 means that we are insensitive to compact H II regions. We find that this estimate of the star formation rate in G305 is consistent with similar estimates made of the star formation rate in Carina (Povich et al. 2011) and M17 (Chomiuk & Povich 2011).

The current star formation rate that we estimate here is also comparable to that derived in Paper II for the Danks clusters. However, we do not consider it likely that G305 has sustained such a star formation rate over its history. If stars had been forming within the G305 complex at a constant rate of  $5 \times 10^{-3} M_{\odot} \text{ yr}^{-1}$  then over 5 Myr we would expect G305 to have formed  $\sim 25000 M_{\odot}$  of stars, which are clearly not detected. It is thus more likely that star formation within the G305 complex has proceeded in a punctuated fashion, with bursts of star formation at different epochs over the history of the complex. The morphology of G305 also suggests a multi-seeded star-forming nature, with several distinct H II regions surrounding the main body of the complex that appear to be unrelated to the intense star formation happening at the rim of the central cavity.

The average star formation rate for the entire Milky Way is estimated at  $\sim 2 M_{\odot} \text{ yr}^{-1}$  (Chomiuk & Povich 2011; Davies et al. 2011). With a star formation rate of between  $10^{-2}$  and

$10^{-3} \text{ M}_{\odot} \text{ yr}^{-1}$  only a few tens to hundreds of complexes like G305, Carina and M17 could make up the bulk of the star formation in the Milky Way. The pinnacle is likely to be dominated by a few much larger complexes, for example the giant H II complexes identified by the *Wilkinson Microwave Anisotropy Probe* (WMAP) that make up half the total Galactic ionizing flux (Murray & Rahman 2010). Just as the luminosity function of stars is dominated by the few most massive stars at the top of the IMF, Galactic star formation is likely dominated by a few massive star-forming complexes.

## 6 SUMMARY

We have surveyed the star-forming complex G305 in search of compact 5.5- and 8.8-GHz radio emission associated with UCH II regions. We find 71 compact radio sources randomly distributed across the observed field (Fig. 1). By matching to GLIMPSE mid-infrared data, we find 15 sources that are associated with G305, six of which we identify as candidate UCH II regions, one as a BRC, eight as stellar radio sources, which leaves 56 background sources.

An analysis of the six candidate UCH II regions reveals radio sources with physical properties consistent with known UCH II regions in five cases. We find typical UCH II properties for these sources, with source radii ranging from 0.04 to 0.1 pc, emission measures  $\sim 2.56\text{--}10.3 \times 10^6 \text{ pc cm}^{-6}$  and electron densities  $\sim 0.34\text{--}1.03 \times 10^4 \text{ cm}^{-3}$ .

By comparing to mid-infrared,  $\text{NH}_3$  molecular line emission,  $\text{H}_2\text{O}$  and methanol masers and the RMS survey, we comment on the star formation history of the region. We find that massive star formation over the last  $10^5$  years, traced by UCH II regions, has taken place around the periphery of the central cavity in close proximity to the ionized and molecular gas interface. Future star formation will most likely occur within the dense  $\text{NH}_3$  clumps surrounding the central cavity. Massive star formation is ongoing and appears to have commenced with the formation of Danks 2 roughly 3–6 Myr ago (Paper II), and the effect of feedback from these clusters has yet to be determined. However, we do find morphological evidence suggestive of triggering. Using the detected UCH II regions we determine a lower limit for the star formation rate in G305 of  $\sim 0.003 \text{ M}_{\odot} \text{ yr}^{-1}$ .

Future Galactic plane surveys will soon provide similar or better quality multi-wavelength data across the extent of the Galaxy. These surveys include  $\text{H}_2\text{O}$  Southern Galactic Plane Survey (HOPS) (Walsh et al. 2008), Co-Ordinated Radio ‘N’ Infrared Survey (COR-NISH) (Purcell & Hoare 2010), Millimetre Astronomy Legacy Team 90 GHz (MALT90) (Foster et al. 2011) and Hi-GAL (Molinari et al. 2010). Using these large samples will allow rigorous statistical studies and resolve some of the long outstanding questions of massive star formation and evolution.

## ACKNOWLEDGMENTS

We thank the anonymous referee for providing suggestions that greatly improved the clarity and quality of this paper. We would like to thank the Director and staff of the Paul Wild Observatory for their assistance with a pleasant and productive observing run. This research has made use of the NASA/IPAC Infrared Science Archive (for access to GLIMPSE), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. This paper made use of information from the Red MSX Source survey data base at [www.ast.leeds.ac.uk/RMS](http://www.ast.leeds.ac.uk/RMS) that was constructed with support from the Science and Technology Facilities Council of the UK.
